\textbf{A B S T R A C T}

We present a probabilistic framework for brittle fracture that builds upon Weibull statistics and strain gradient plasticity. The constitutive response is given by the mechanism-based strain gradient plasticity theory, aiming to accurately characterize crack tip stresses by accounting for the role of plastic strain gradients in elevating local strengthening ahead of cracks. It is shown that gradients of plastic strain elevate the Weibull stress and the probability of failure for a given choice of the threshold stress and the Weibull parameters. The statistical framework presented is used to estimate failure probabilities across temperatures in ferritic steels. The framework has the capability to estimate the three statistical parameters present in the Weibull-type model without any prior assumptions. The calibration against experimental data shows important differences in the values obtained for strain gradient plasticity and conventional J2 plasticity. Moreover, local probability maps show that potential damage initiation sites are much closer to the crack tip in the case of gradient-enhanced plasticity. Finally, the fracture response across the ductile-to-brittle regime is investigated by computing the cleavage resistance curves with increasing temperature. Gradient plasticity predictions appear to show a better agreement with the experiments.

1. Introduction

Macroscopic fracturing in metallic materials depends sensitively on properties that pertain to the micro and atomic scales. Not surprisingly, a considerable effort has been made to link scales in fracture mechanics, with the ultimate goal of quantitatively predicting the strength, durability, and reliability of structural components (Suo et al., 1993; Hutchinson, 1997). These endeavours aim at spanning the wide range of scales at stake by enriching continuum theories to properly characterize behaviour at the small scales involved in crack tip deformation.

The deficiencies intrinsic to conventional plasticity theory provide a strong motivation for developing mechanistically-based models. Namely, unrealistically low stresses are predicted ahead of the crack tip, with toughness being unbounded for cohesive strengths of approximately 3 times the initial tensile yield stress in a perfectly plastic material ($\gamma/\sigma_t \rightarrow 3$ in a mild hardened solid, see Tvergaard and Hutchinson, 1992). Opening stresses on the order of 3–5 times the initial tensile yield stress fail to explain decohesion at the atomic scale. Cleavage fracture in the presence of significant plastic flow has been empirically observed in numerous material systems (Elssner et al., 1994; Bagchi and Evans, 1996; Korn et al., 2002). Since atomic separation requires traction levels on the order of the theoretical lattice strength ($10\sigma_t$ or larger), classic continuum theories would appear to rule out a fracture mechanism based on atomic decohesion whenever plasticity develops in the vicinity of the crack. Moreover, conventional plasticity predictions reveal important discrepancies with separation strengths calculated from first principles (Raynolds et al., 1996), and toughness bounds attained by discrete dislocation dynamics (Cleveringa et al., 2006; Irani et al., 2017), highlighting the need to bridge the gap between macroscopic modelling of cracking and the microstructural and atomistic mechanisms of fracture.

Small scale experiments have consistently shown that conventional plasticity theory is unable to characterize the material response of metals at the micro level. Fostered by growing interest in microtechnology, a wide range of mechanical tests on micro-sized specimens have revealed that metallic materials display strong size effects when deformed non-uniformly into the plastic range. Experiments such as indentation (Nix and Gao, 1998), torsion (Fleck et al., 1994), or bending (Stölken and Evans, 1998) predict a 3-fold increase in the effective flow stress by reducing specimen size (\textit{smaller is stronger}). This size effect is attributed to gradients of plastic strain that require a definite density of dislocations to accommodate lattice curvature (Ashby, 1970). These geometrically necessary dislocations (GNBs) are not accounted for in conventional theories of plasticity, neglecting the length

scale dependency intrinsically associated with plastic flow. A large theoretical literature has appeared seeking to extend plasticity theory to small scales by the development of isotropic strain gradient plasticity (SGP) formulations (Aifantis, 1984; Gao et al., 1999; Fleck and Hutchinson, 2001; Anand et al., 2005). Using SGP theories to provide an implicit multi-scale characterization of the mechanical response ahead of a crack appears imperative as, independently of the size of the specimen, the plastic zone adjacent to the crack tip is physically small and contains strong spatial gradients of deformation (Martínez-Pañeda and Betegón, 2015). The investigation of stationary crack tip fields has shown that plastic strain gradients promote local strain hardening and lead to much higher stresses relative to classic plasticity predictions (Jiang et al., 2001; Wei, 2006; Komaragiri et al., 2008; Martínez-Pañeda et al., 2017b). Accurately capturing crack tip stresses has proven to be fundamental in predicting fatigue damage (Gil-Sevillano, 2001; Brinckmann and Siegmund, 2008; Prie et al., 2019), notch fracture mechanics (Martínez-Pañeda et al., 2017a), microvoid cracking (Tvergaard and Niodson, 2008), and hydrogen assisted failure (Martínez-Pañeda et al., 2016a, b). Since plastic strain gradients can alter crack tip stresses over several tens of μm, it is expected that strain gradient plasticity models will also play an important role in the modelling of cleavage fracture and the ductile-to-brittle transition (Martínez-Pañeda et al., 2019; Qian et al., 2011).

Cleavage fracture models are grounded on the concept of micro-cracks nucleating from defects, such as inclusions or second-phase particles (Pineau et al., 2016). The location of these defects is statistical by nature and, consequently, modelling efforts rely mainly on probabilistic analysis. The seminal work by the Beremin group (Beremin, 1983) established the fundamental framework on which most cleavage models stand; Weibull statistics and the weakest link model are employed to estimate the probability of failure (Section 2.4). The implementation is carried out by coupling a general constitutive equation for dimensional consistency. The value of μ, it is expected that strain gradient plasticity predictions are compared with results from conventional plasticity predictions will influence failure probability predictions.

In this work, we make use of a mechanism-based strain gradient plasticity formulation to accurately characterize crack tip stresses. The constitutive description is coupled with a probabilistic framework capable of obtaining all the statistical parameters of the model without any prior assumptions. The capabilities of the present mechanism-based scheme for probabilistic analysis of brittle fracture are benchmarked against experimental data from the Euro toughness project (Heerens and Hellmann, 2002). Experiments are reproduced over a wide range of temperatures, so as to span the ductile-to-brittle regime. Strain gradient plasticity predictions are compared with results from conventional plasticity and insight is gained into the role of the stress elevation due to strain gradients in assessing cleavage.

2. Numerical model

The implicitly multi-scale statistical framework for brittle fracture presented stands on a Taylor-based strain gradient plasticity formulation (Section 2.1), and a three-parametric Weibull type statistical model (Section 2.2). The implementation is carried out by coupling a general purpose finite element program with the statistical tools of Matlab, see Section 2.3. An experimental campaign employing Compact Tension specimens will be reproduced to highlight the capabilities of the model (Section 2.4).

2.1. Mechanism-based strain gradient plasticity

We model strain gradient effects by means of the so-called mechanism-based strain gradient (MSG) plasticity theory (Gao et al., 1999; Qian et al., 2003). MSG plasticity is grounded on Taylor's dislocation density. In these models the stress level is the driving force for fracture and, consequently, local strengthening due to plastic strain gradients will influence failure probability predictions.

\[ \tau = \alpha \mu b \sqrt{f} \]  \hspace{1cm} (1)

where \( \mu \) is the shear modulus, \( b \) is the magnitude of the Burgers vector and \( \alpha \) is an empirical coefficient that is taken to be equal to 0.5. The dislocation density is additively composed of the density \( \rho_{\text{GND}} \) for statistically stored dislocations (SSDs) and the density \( \rho_{\text{S}} \) for geometrically necessary dislocations (GNDs), \( \rho = \rho_{\text{GND}} + \rho_{\text{S}} \) \hspace{1cm} (2)

The GND density \( \rho_{\text{GND}} \) is related to the effective plastic strain gradient \( \eta^p \) by

\[ \rho_{\text{GND}} = \frac{f \eta^p}{b} \]  \hspace{1cm} (3)

where \( f \) is the Nye-factor which is assumed to be 1.90 for face-centred-cubic (fcc) polycrystals. Gao et al. (1999) used three quadratic invariants of the plastic strain gradient tensor to represent the effective plastic strain gradient \( \eta^p \) as

\[ \eta^p = \sqrt{c_1 \eta_{ik}^p \eta_{ik}^p + c_2 \eta_{ik}^p \eta_{jk}^p + c_3 \eta_{ik}^p \eta_{jk}^p} \]  \hspace{1cm} (4)

The coefficients were determined to be equal to \( c_1 = 0, c_2 = 1/4 \) and \( c_3 = 0 \) from three dislocation models for bending, torsion and void growth. Accordingly, \( \rho_{\text{GND}} = \frac{1}{\sqrt{4 \eta_{ik}^p \eta_{ik}^p}} \) \hspace{1cm} (5)

The components of the strain gradient tensor are obtained from \( \eta_{ik}^p = \eta_{ik}^p - \eta_{ij}^p \) \hspace{1cm} (6)

The tensile flow stress \( \sigma_{\text{flow}} \) is related to the shear flow stress \( \tau \) by

\[ \sigma_{\text{flow}} = M \tau \]  \hspace{1cm} (7)

with \( M \) denoting the Taylor factor, which equals 3.06 for fcc metals. Rearranging (1–3) and substituting into (7) renders

\[ \sigma_{\text{flow}} = M \alpha \mu b \sqrt{\rho_{\text{S}} + \frac{f \eta^p}{b}} \]  \hspace{1cm} (8)

The SSD density \( \rho_{\text{S}} \) can be readily determined from (8) knowing the relation in uniaxial tension between the flow stress and the material stress-strain curve,

\[ \rho_{\text{S}} = \left[ \alpha_{\text{ref}} f (\varepsilon^p)/(M \alpha \mu b) \right]^2 \]  \hspace{1cm} (9)

Here, \( \alpha_{\text{ref}} \) is a reference stress and \( f \) is a non-dimensional function of the plastic strain \( \varepsilon^p \), as given by the uniaxial stress-strain curve. Substituting into (8), the flow stress \( \sigma_{\text{flow}} \) reads

\[ \sigma_{\text{flow}} = \alpha_{\text{ref}} \sqrt{f^2 (\varepsilon^p)} + \varepsilon \eta^p \]  \hspace{1cm} (10)

where \( \varepsilon \) is the intrinsic material length parameter that enters the constitutive equation for dimensional consistency. The value of \( \varepsilon \) can be obtained by fitting micro-scale experiments and typically ranges between 1 and 10 μm. The model recovers the conventional plasticity solution when \( \varepsilon = 0 \).

2.2. Weibull three-parametric

We present a statistical framework that has the capability of predicting brittle and ductile failure and requires no prior assumptions (Muttil-Calvente et al., 2015; Papazafeiropoulos et al., 2017). First, for a given Weibull stress \( \sigma_\theta \) and a threshold stress for crack growth \( \sigma_0 \), the cumulative probability of failure \( P_f \) is given by

\[ P_f = 1 - \exp \left[ - \left( \frac{\sigma_\theta - \sigma_0}{\sigma_0} \right)^m \right] \]  \hspace{1cm} (11)

where \( \sigma_\theta \) and \( m \) respectively denote the scaling parameter and the modulus. Equation (11) is defined in (Beremin, 1983) without \( \sigma_0 \) but
stresses smaller than the yield stress were considered innocuous, implying the assumption of \( \sigma_{0} = \sigma_{y} \). A global Weibull stress is defined based on weakest link considerations

\[
\sigma_u = \sigma_0 + \left[ \sum_{i=1}^{n} (\sigma_i - \sigma_0)^m (V_i / V_0) \right]^{1/m} \tag{12}
\]

Here \( V_0 \) is a reference volume, \( V_i \) is the volume of the \( ith \) material unit in the fracture process zone experiencing a maximum principal stress \( \sigma_i \), and \( n_i \) is the number of finite elements/material units in the fracture process zone. The parameter \( \sigma_0 \) is needed due to the fact that cracks do not propagate below a certain threshold energy value. However, the concurrent estimation of the threshold, modulus and shape parameters remains a complicated task; a common approach lies in assuming a value for \( \sigma_0 \) and estimating \( m \) and \( \sigma_u \) from a set of experiments by means of the maximum likelihood method (Muniz-Calvente et al., 2016a,b). Here, all three parameters \((\sigma_0, m, \sigma_u)\) will be obtained by means of the following procedure (see Fig. 1):

1) First, the probability of failure is computed for all the experiments conducted at a given temperature. The \( P_f \) versus load curve, where the load is expressed in terms of the \( J \)-integral, is computed by means of

\[
P_f = \frac{j-0.3}{n_j+0.4} \tag{13}
\]

where \( n_j \) denotes the number of experiments for a given temperature and \( j \) is the rank number.

2) A finite element analysis is conducted, and the values of \( \sigma_i \) and \( V_i \) are computed at each element for the set of critical \( J_i \) at which failure has been reported in the experiments. The domain integral method is used to compute the value of \( J_i \) in each load increment.

3) The least squares method is employed to fit the Weibull distribution by using cumulative probabilities. Since the threshold parameter \( \sigma_0 \) is also an unknown, the procedure requires iterating over the following steps:

3.1) The Weibull stress \( \sigma_u \) is first computed according to (12) from the information provided by the finite element model (Step 2). In (12), \( m \) and \( \sigma_u \) correspond to the values of the previous iteration (or an initial estimate, in the case of the first iteration).

3.2) The Weibull stress \( \sigma_u \) is introduced in (11) and the values of \( \sigma_u \), \( m \) and \( \sigma_0 \) in the current iteration are computed by fitting a univariate distribution using least squares estimates of the cumulative distribution functions. Namely, the cumulative probability of failure (11) is written as,

\[
\log(\sigma_u) + \log(-\log(1 - P_f)) - \frac{1}{m} = \log(\sigma_u - \sigma_0) \tag{14}
\]

introducing a linear relationship between \( \log(-\log(1 - P_f)) \) and \( \log(\sigma_u - \sigma_0) \). From the \( P_f \) assigned to each load (Step 1) and the Weibull stress computed for each of those loads (Step 2), we make use of least squares to fit this straight line on the transformed scale. The slope and intercept of the line provide with the values of \( m \) and \( \sigma_u \) for a given \( \sigma_0 \). The quality of the fit will be given by the choice of \( \sigma_0 \); we find the optimum by maximizing the coefficient of determination \( R^2 \) over all possible threshold values. The optimum value of \( \sigma_0 \) is specific to the current iteration and associated values of \( m \) and \( \sigma_u \).

3.3) The procedure is repeated until convergence is achieved. We assume that the solution has converged when the following criterion has been met

\[
\frac{|(m)_i - (m)_{i-1}|}{(m)_i} + \frac{|(\sigma_u)_i - (\sigma_u)_{i-1}|}{(\sigma_u)_i} < 0.0001 \tag{15}
\]

where \( (m)_i \) denotes the value of \( m \) in the current increment while the subscript \( i - 1 \) represents its value in the previous increment. Consequently, the outcome of the analysis is the threshold value below which cracking will not occur \( \sigma_0 \), along with the two Weibull parameters \( m \) and \( \sigma_u \). A stress level of \( \sigma_u + \sigma_0 \) will denote a 63% failure probability in a given material unit element.

Fig. 1. Flowchart describing the combined experimental-computational-statistical procedure for estimating the three Weibull parameters \( \sigma_0, m, \) and \( \sigma_u \).
2.3. Numerical implementation

The framework presented in Sections 2.1 and 2.2 is numerically implemented by exploiting Abaqus2Matlab (Papazafeiropoulos et al., 2017). Hence, we run the commercial finite element package Abaqus within the mathematical software Matlab to take advantage of Matlab’s in-built capabilities for fitting univariate distributions by means of the least squares method.

We implement MSG plasticity in the commercial finite element package Abaqus by means of a user material subroutine (UMAT). For numerical reasons, we make use of the lower order version of MSG plasticity, commonly referred to as the conventional mechanism based strain gradient (CMSG) plasticity theory (Huang et al., 2004). As shown in (Martínez-Pañeda and Niordson, 2016) and discussed in (Shi et al., 2001), the lower and higher order versions of MSG plasticity predict identical results except for a boundary layer of size roughly 10 nm. This boundary layer falls outside of the domain of physical validity of continuum theories; strain gradient plasticity models a collective behaviour of dislocations and it is therefore applicable at a scale much larger than the dislocation spacing. Fortran modules are used to store the plastic strain components across Gauss integration points, and the plastic strain gradient is computed by numerical differentiation within the element. First, the plastic strain increment is interpolated through its values at the Gauss points in the isoparametric space, and afterwards the increment in the plastic strain gradient is calculated by differentiation of the shape functions. The reader is referred to (Martínez-Pañeda et al., 2017a) for more details.

2.4. Boundary value problem

We employ our framework to assess brittle failure in ferritic steels. Numerical predictions are compared to experimental results from the Euro toughness project on DIN 22NiMoCr37 steel (Heerens and Hellmann, 2002). The finite element model includes the compact tension specimen and the pins. The load is prescribed by imposing a displacement on the pins, and we model contact between the pins and the specimen by using a surface to surface contact algorithm with finite strain. The path independent J-integral is computed outside of the plastic zone by means of the domain integral method at each load increment. An initial blunting radius of 2 μm is defined at the crack tip. After a mesh sensitivity analysis, the specimen is discretized with 9800 quadrilateral quadratic plane strain elements. As shown in Fig. 2, a very refined mesh is used near the crack tip so as to accurately capture the influence of plastic strain gradients.

3. Results

We begin our analysis by investigating the stress elevation of strain gradient plasticity and its influence on the Weibull stress distribution (Section 3.1). Then, we calibrate the Weibull parameters for each temperature and assess the probability of failure due to cleavage with both conventional and MSG plasticity theories (Section 3.2). Section 3.3 explores the response across temperatures aiming to gain insight into the role of plastic strain gradients in the ductile-to-brittle transition. First, we define our uniaxial stress-strain hardening law as

\[ \sigma = \sigma_Y \left( 1 + \frac{\varepsilon^p}{\sigma_Y} \right)^N \]  

where \( N \) is the strain hardening exponent. Thus, in (10), the reference stress equals \( \sigma_Y = \left( \frac{\varepsilon}{\sigma_Y} \right)^N \) and \( f(\varepsilon^p) = \left( \varepsilon^p + \frac{\varepsilon}{\sigma_Y} \right)^N \). Here, Young’s modulus takes the value \( E = 200 \) GPa, and Poisson’s ratio equals \( \nu = 0.3 \). We proceed to calibrate \( N \) and \( \sigma_Y \) with the uniaxial stress-strain data available as part of the Euro toughness data set (Heerens and Hellmann, 2002). The values of yield stress \( \sigma_Y \) and strain hardening exponent \( N \) obtained at each temperature are listed in Table 1. A representative fit is shown in Fig. 3a for the case of a temperature of \( T = −40 \) °C. As shown in Table 1, both \( \sigma_Y \) and \( N \) decrease with increasing temperature, in agreement with expectations. One should note that the length scale parameter of MSG plasticity has shown a negligible sensitivity to changes in temperature, as measured by Qian et al. (2014) through nanoindentation. Hence, we consider an intermediate value of \( \varepsilon = 5 \) μm for all temperatures (Martínez-Pañeda and Niordson, 2016).

The computation of the force versus displacement curves from the calibrated values of \( \sigma_Y \) and \( N \) shows a good agreement with the experimental data. The results obtained for the representative case of \( T = −40 \) °C are shown in Fig. 3b. The influence of the plastic strain gradients is restricted to a small region next to the crack tip and, consequently, the macroscopic force versus displacement curve is almost insensitive to \( \varepsilon \) in the absence of damage. Locally, crack tip stresses are however very sensitive to local strengthening due to gradients of plastic strain.

3.1. Gradient effects on crack tip stresses

We examine first the tensile stress distribution ahead of the crack for a representative case, \( T = −40 \) °C, and a specific load level that falls within the range of critical loads reported in the experiments, \( J = 290 \) N/mm. Results are shown in Fig. 4 for both conventional and MSG
plasticity with $\ell = 5$ $\mu$m. The tensile stress is normalized by the yield strength of the material at $T = -40^\circ$C, and the distance ahead of the crack is shown in logarithmic scale to highlight the different responses given by MSG and conventional plasticity theories. As shown in the figure, far away from the crack tip both MSG plasticity and conventional $J_2$ plasticity agree but differences start at about 20–30 $\mu$m ahead of the crack. This distance is sufficiently large to engulf the critical length of various damage mechanisms, including cleavage in ferritic steels. The stress elevation due to plastic strain gradients is associated with large geometrically necessary dislocation (GND) densities that act as obstacles to the motion of statistically stored dislocations and elevate local strength.

The stress elevation associated with large gradients of plastic strain in the vicinity of a crack influences cleavage models by elevating the Weibull stress $\sigma_w$. We illustrate this by assuming $m = 3$ and $a_{th} = 2.5\sigma_Y$ and computing the Weibull stress through (12) as a function of the remote load. Results are shown in Fig. 5 for two representative values of the length scale parameter $\ell = 5$ $\mu$m and $\ell = 10$ $\mu$m, as well as for conventional plasticity. As shown in the figure, the Weibull stress $\sigma_w$ increases with increasing $\ell$ and differences increase with the remote load. As we shall show below, differences are sensitive to the values of $m$ and $a_{th}$, and the gradient-enhanced $\sigma_w$ elevation can be substantial. Note that, following (11), strain gradient plasticity elevates the local probability of failure for a fixed value of $a_{th}, a_{th}$ and $m$.

### 3.2. Statistical analysis of cleavage

The statistical framework outlined in Section 2 is now employed to estimate the probability of failure as a function of the remote load, as quantified by $J$. Fig. 6 shows the results obtained for 4 representative

---

**Fig. 3.** Calibration of material properties: (a) Uniaxial stress-strain response, and (b) force versus displacement curve in a CT specimen. The case of temperature $T = -40^\circ$C is chosen as representative.
temperatures, $T = -154\, ^\circ C$, $T = -91\, ^\circ C$, $T = -60\, ^\circ C$ and $T = -40\, ^\circ C$. The figure shows the experimental predictions, as given by (13), along with the results for MSG plasticity with $\ell = 5\, \mu m$ and conventional J2 plasticity. Both conventional and MSG plasticity predictions exhibit good agreement with the experiments for the calibrated Weibull parameters.

The calibrated values of the modulus $m$, the threshold stress for crack growth $\sigma_{th}$, and the scaling parameter $\alpha$ are shown in Table 2. Results are shown for 7 temperatures and both strain gradient and conventional plasticity. Considering the effect of plastic strain gradients leads to very significant differences in the values of the calibrated Weibull parameters (see, e.g., Ruggieri et al., 2000) is addressed by repeating the procedure for four different geometries (0.5, 1, 2 and 4 T) and two temperatures ($-91\, ^\circ C$ and $-20\, ^\circ C$). Computations reveal very similar values of $m$, $\alpha_{th}$ and $\alpha$ to those shown in Table 2 for both conventional and strain gradient plasticity. Differences are largest with geometry 4 T but remain below 10% in all cases.

More insight into the influence of plastic strain gradients on local failure probability can be gained by means of a hazard map. In a hazard map, the local probability of failure is shown over the entire engineering component, highlighting the areas that are vulnerable to a specific type of failure (Muñiz-Calvente et al., 2016a,b). The local probability of failure is computed as $P_f$ in each material unit $l$ from a local $\sigma$. The results obtained are shown in log scale in Fig. 7 for both conventional and strain gradient plasticity. Important differences can be readily observed. While the local $P_f$ only becomes meaningful close to the crack tip in both cases, the potential damage initiation sites are identified to be much more localized for the case of strain gradient plasticity. In other words, only defects within tens of microns, as opposed to several mm, are identified as fracture-triggering particles when plastic strain gradients are accounted for. The critical distance for cleavage fracture in steels is considered to be significantly smaller than 1 mm (Watanabe et al., 1987).

### 3.3. The ductile to brittle transition

We then proceed to examine the ductile-to-brittle transition by computing the resistance curves for $P_f = 0.1$, 0.5 and 1 across the temperature versus load map. For each value of $P_f$ three curves are shown, the experimental data and the numerically computed results for MSG plasticity and conventional J2 plasticity; see Fig. 8. The results show how the load at which failure is predicted, $P_f = 0.5$, increases with the temperature - ductility is enhanced. As the load and the temperature increase, ductile crack growth is observed, with the largest temperatures showing several cases where crack extension equals $\Delta a = 2\, mm$, the limit value for ductile growth tests (Heerens and Hellmann, 2002).

In addition, the gradient-enhanced prediction appears to follow more precisely the experimental trend.

### 3.4. Influence of crack tip constraint conditions

Lastly, we investigate the influence of crack tip constraint conditions by imposing a non-zero elastic T-stress (Betegon and Hancock, 1991). This is achieved by means of the so-called modified boundary layer formulation. Consider a crack plane aligned with the negative $x_1$ axis of the Cartesian reference frame $(x_1, x_2)$. For a crack tip placed at the origin and a given T value, we choose to prescribe a remote mode I load, $K_1$, by defining the nodal displacements in the outer periphery of temperature. While the strain gradient plasticity-based prediction exhibits the natural trend of decreasing $\alpha_{th}$ with decreasing T (the material anticipates a reduced barrier to cleavage), this is not the case for conventional plasticity. 

A plausible explanation behind the scatter observed lies on the fact that the maximum tensile stress is load-independent in conventional plasticity (McMeeking, 1977); for lower temperatures, a higher stress level is attained for the same $J$ as $\sigma_t$ is larger. Contrarily, in strain gradient plasticity, crack tip stresses scale with the remote load (Martínez-Pañeda and Fleck, 2019). 

In addition, the conventional plasticity results show noticeably high predictions for $m$ at temperatures $-60\, ^\circ C$ and $-40\, ^\circ C$. For these two temperatures, there is a clear change in the shape of the $P_f$ versus $J$ curve for values of $P_f$ close to 0.75. Reducing the tolerance of the convergence criterion or changing the initial estimations of $m$ and $\alpha_{th}$ did not have any influence on the outcome of the statistical fitting procedure. Moreover, very similar results were obtained when repeating the procedure with specimens of different geometry; referred to as 0.5 T and 1 T in (Heerens and Hellmann, 2002). The uniqueness of the Weibull parameters (see, e.g., Ruggieri et al., 2000) is addressed by repeating the analysis for four different geometries (0.5, 1 T, 2 T and 4 T) and two temperatures ($-91\, ^\circ C$ and $-20\, ^\circ C$). Computations reveal very similar values of $m$, $\alpha_{th}$ and $\alpha$ to those shown in Table 2 for both conventional and strain gradient plasticity. Differences are largest with geometry 4 T but remain below 10% in all cases.

Weibull stress dependence on the remote load for both MSG plasticity, with $\ell = 5\, \mu m$ and $\ell = 10\, \mu m$, and conventional plasticity. The case of temperature $T = -40\, ^\circ C$ is chosen as representative.

For a crack tip placed at the origin and a given T value, we choose to prescribe a remote mode I load, $K_1$, by defining the nodal displacements in the outer periphery of the crack plane ($x_5 = 0$) for both MSG plasticity and conventional plasticity at $J = 290\, N/mm$. The distance ahead of the crack tip is given in logarithmic scale. The case of temperature $T = -40\, ^\circ C$ is chosen as representative.
Fig. 6. Failure probability as a function of the external load. The figure includes the experimental data for 22NiMoCr37 steel (Heerens and Hellmann, 2002) and the predictions from the present statistical model for the values of $\alpha_u$, $\alpha_t$, and $m$ listed in Table 2. Temperatures (a) $T = -154$ °C, (b) $T = -91$ °C, (c) $T = -60$ °C and (d) $T = -40$ °C are chosen as representative.

Fig. 7. Hazard map, showing the local probability of failure in log scale at each material unit for the case of $T = 40^\circ C$ and $J = 282.2$ N/mm.
the mesh as

\[ u_1(r, \theta) = K_1 \frac{1 + \nu}{E} \sqrt{\frac{r}{2\pi}} \cos \left( \frac{\theta}{2} \right) \left( 3 - 4\nu - \cos 2\theta \right) + T \left( \frac{1 - \nu^2}{E} \right) r \cos \theta \]

\[ u_2(r, \theta) = K_1 \frac{1 + \nu}{E} \sqrt{\frac{r}{2\pi}} \sin \left( \frac{\theta}{2} \right) \left( 3 - 4\nu - \cos 2\theta \right) - T \left( \frac{\nu(1 + \nu)}{E} \right) r \sin \theta \]

where \( r \) and \( \theta \) are polar coordinates centred at the crack tip. As shown in Fig. 9, upon exploiting symmetry about the crack plane, only half of the model is analysed. We introduce an initial blunting radius that is \( 10^5 \) times smaller than the outer radius. The modified boundary layer model is discretized by means of 6422 quadrilateral quadratic plane strain elements.

The results obtained, in terms of Weibull stress \( \sigma_w \) versus remote load \( K_I \) are shown in Fig. 10. As in Fig. 5, we consider a temperature of \( T = 40 \) °C and assume \( m = 3 \) and \( \alpha_h = 2.5 \mu \). A range of 3 values of the T-stress is considered: \( T/\sigma_Y = -0.5 \), \( T/\sigma_Y = 0 \), and \( T/\sigma_Y = 0.5 \). The same qualitative trends are obtained for both conventional plasticity and strain gradient plasticity; for a given remote load \( K_I \), the Weibull stress increases with increasing \( T \). However, conventional plasticity predictions of \( \alpha_w \) appear to exhibit a higher sensitivity to crack tip constraint conditions for the values of \( m \) and \( \alpha_h \) assumed.

4. Conclusions

We have presented a 3-parameter statistical framework for cleavage that incorporates the role of large plastic strain gradients in the characterization of crack tip stresses. The model enables to accurately compute Weibull stresses and calibrate - without any prior assumptions - the three statistical parameters: threshold stress \( \alpha_h \), scaling parameter \( \alpha_u \) and modulus \( m \). Finite element analysis is used in combination with Weibull statistics to investigate cleavage in ferritic steels with both conventional J2 plasticity and the mechanism-based strain gradient (MSG) plasticity theory. The main findings are:

i) For given values of \( \alpha_h \), \( \alpha_u \) and \( m \), strain gradient plasticity effects elevate the Weibull stress and the probability of failure.

ii) The calibrated Weibull parameters for MSG plasticity show significant differences with the values obtained with conventional plasticity. The threshold stress required to trigger cracking in the gradient-enhanced case is 2–8 times larger than its conventional plasticity counterpart.

iii) Hazard maps, where the probability of failure is shown in each material unit, show that defects susceptible of initiating cracking are confined in a much smaller region next to the crack tip in the strain gradient plasticity case.

iv) The probability of failure is computed across the ductile-to-brittle transition, with strain gradient plasticity predictions showing a better agreement with experiments.
Acknowledgements

The authors acknowledge valuable discussions with M. Muñiz-Calvente (University of Oviedo).
